Abstract

The continuous use of the web for daily operations by businesses, consumers, and government has created a great demand for reliable web applications. One promising approach to testing the functionality of web applications leverages user session data collected by web servers. This approach automatically generates test cases based on real user profiles. The key contribution of this paper is the application of concept analysis for clustering user sessions for test suite reduction. Existing incremental concept analysis algorithms can be exploited to avoid collecting large user session data sets and thus provide scalability. We have completely automated the process from user session collection and reduction through replay. Our incremental test suite update algorithm coupled with our experimental study indicate that concept analysis provides a promising means for incrementally updating reduced test suites in response to newly captured user sessions, with some loss in fault detection capability and practically no coverage loss.

1. Introduction

As the quantity and breadth of web-based software systems continue to grow at a rapid pace, the issue of assuring the quality and reliability of this software domain is becoming critical. Low reliability can result in serious, detrimental effects for business, government, and consumers, as they have become increasingly dependent on the internet for routine daily operations. A major impediment to producing reliable software is the labor and resource intensive nature of software testing. A short time to market dictates little motivation for time consuming testing strategies. For web applications, testing is complicated by additional challenges beyond the analysis and testing considerations associated with more traditional modes of testing.

Many of the current testing tools are for addressing web usability, performance, and portability issues [34]. For example, link testers navigate a web site and verify that all hyperlinks refer to valid documents. Form testers create scripts that initialize a form, press each button, and type preset scripts into text fields, ending with pressing the submit button. Compatibility testers ensure that a web application functions properly within different browsers.

For testing the functionality of Java-based web programs, tools, such as Cactus [4] which utilizes JUnit [15], provide test frameworks for unit testing. In addition, web-based analysis and testing tools have been developed that model the underlying structure and semantics of web programs [21, 22, 30], towards a white-box approach to testing. While these white-box techniques enable the extension of the path-based testing to web applications, they often require identifying input data that will exercise the paths to be tested, which are not covered by test cases generated from functional specifications.

One approach to testing the functionality of web applications that addresses the problems of the path-based approaches is to utilize capture and replay mechanisms which record user-induced events, gathering and converting them into scripts, which are then replayed for testing[9, 28]. Tools such as WebKing[26] and Rational Robot[28] provide automated testing of web applications by collecting data from users through minimal configuration changes to the web server. The recorded events are typically URLs and name-value pairs sent as requests to the web server. The ability to record these requests is often built into the web server, so little effort is needed to record the desired events. In a controlled experiment, Elbaum, Karre, and Rothermel[9] showed that user session data can be used to generate test suites that are as effective overall as suites generated by two implementations of Ricca and Tonella’s white-box techniques[30]. This provides a promising approach to testing the functionality of web applications which relieves the tester from having to generate the input
data manually, and provides a way to enhance an original test suite with test data that represents usage as the operational profile of the application evolves. Unfortunately, the fault detection capability appears to increase with larger numbers of captured user sessions, but the test preparation and execution time quickly becomes impractical. While existing test reduction techniques[13] can be applied to reduce the number of test cases that are maintained, the initial overhead of selection and analysis of the large user session data sets is non-scalable.

This paper presents an approach for achieving scalable user session-based testing of web applications. The collection of logged user sessions can be viewed as a set of use cases where a use case is a behaviorally related sequence of events performed by the user through a dialogue with the system [14]. The key insight is the formulation of the test case reduction problem for user session testing in terms of concept analysis. Existing incremental concept analysis techniques can then be exploited to analyze the user sessions on the fly, as sessions are captured and converted into test cases, and thus continually reflect the set of use cases representing actual executed user behavior by a minimal test suite. Test case reduction is being accomplished on the fly by grouping user sessions into similar clusters. Through the creative use of a number of existing tools and the development of some simple scripts, we have automated the entire process from gathering user sessions through the identification of a reduced test suite and replay of that test suite for coverage analysis and fault detection. In our experiments, the resulting coverage provided by the reduced test suite is almost identical to the original suite of user sessions, with some loss in fault detection.

After providing background in Section 2, we describe formulation of the test case reduction problem for user session based testing as a concept analysis problem in Section 3. In Section 4, we present our incremental reduced test suite update algorithm which utilizes existing incremental concept analysis techniques. Section 5 presents our complete framework for automatic test case generation, coverage analysis and fault detection for web testing. Section 6 presents the research questions, setup, methodology and results of an experimental study which focused on the cost effectiveness of this approach in terms of test case reduction, and maintaining coverage and fault detection capability. Related work is included in Section 7 followed by conclusions and future work in Section 8.

2. Background

2.1. Web Applications

Broadly defined, a web-based software system consists of a set of web pages and components that interact to form a system which executes using web server(s), network, HTTP, and a browser, and in which user input (navigation and data input) affects the state of the system. A web page can be either static, in which case the content is fixed, or dynamic, such that its contents may depend on user input.

Web applications may have a number of characteristics, including: an integration of numerous technologies; modularization into reusable components that may be constructed by third parties; a well-defined, layered architecture; dynamically generated pages with dynamic content; and typically extend an application framework. Large web-based software systems can require thousands to millions of lines of code, contain many interactions among objects, and involve significant interaction with users. In addition, changing user profiles and frequent small maintenance changes complicate automated testing [16].

2.2. User-session Testing

In user-session based testing, data is collected from users of a web application by the web server. Each user session is a collection of user requests in the form of URL and name-value pairs. More specifically, user sessions are defined as beginning when a request from a new IP address reaches the server and ending when the user leaves the web site or the session times out.

To transform a user session into a test case, each logged request of the user session is changed into an HTTP request that can be sent to a web server. A test case consists of a set of HTTP requests that are associated with each user session. Different strategies are applied to construct test cases for the collected user sessions. A key advantage is the minimal configuration changes that need to be made to the web server in order to collect user requests.

Elbaum et al. [9] provide promising results that demonstrate the fault detection capabilities and cost-effectiveness of user session testing. In particular, they show user session techniques are able to uncover certain types of faults, but faults associated with rarely entered data are not uncovered. In addition, they show that the effectiveness of user session techniques improves as the number of collected sessions increases. However, the cost of collecting, analyzing, and replaying test cases also increases. With Harrold et al.’s. [13] test case reduction technique, Elbaum et al. [9] report that they are able to achieve a high percent of test case reduction. However, current test case reduction techniques are based on performing the test reduction over a complete test set. All the user session data is collected before the reduction process occurs. An incremental update is not performed as test cases are added.
2.3. Concept Analysis

Concept analysis is a mathematical technique for clustering objects that have common discrete attributes[3]. Concept analysis takes as input a set O of objects, a set A of attributes, and a binary relation R ⊆ O × A, called a context, which relates the objects to their attributes. The relation R is implemented as a boolean-valued table in which there exists a row for each object in O and a column for each attribute in A; the entry of table[o, a] is true if object o has attribute a, otherwise false.

Concept analysis identifies all of the concepts for a given tuple (O, A, R), where a concept is a tuple t = (Oi, Ai) for which all and only objects in Oi share all and only attributes in Ai. The concepts form a partial order defined as (Oi, Ai) ≤ (O2, A2), if O1 ⊆ O2. Similarly, the lattice can be viewed as a superset relation on the attributes, as (O1, A1) ≤ (O2, A2), iff A1 ⊆ A2. The set of all concepts of a context and the partial ordering form a complete lattice, called the concept lattice, which can be represented by a directed acyclic graph with a node for each concept and edges denoting the ≤ partial ordering. The top element ⊤ of the concept lattice is the most general concept, with the set of all of the attributes that are shared by all objects in O. The bottom element ⊥ is the most special concept with the set of all of the objects that have all of the attributes in A.

3. Applying Concept Analysis

To apply concept analysis to user session based testing, we use objects to represent user sessions (i.e., test cases) and attributes to represent URLs. While a user session is considered to be a set of URLs and associated name-value pairs for accurate replay, we define a user session during concept analysis to be the set of URLs requested by the user, without the name-value pairs, and without any ordering on the URLs. This considerably reduces the number of attributes to be analyzed. We present evidence of the effectiveness of choosing single URLs as attributes in [31]. A pair (user session s, URL u) is in the binary relation iff s requests u. Thus, each true entry in a row r of the relation table represents a URL that the single user represented by row r requests. For column c, the set of true entries represents the set of users who have requested the same URL, of column c.

As an example, the relation table in Figure 1(a) shows the context for a user session based test suite for a portion of a bookstore web application [11]. User sessions are uniquely identified by the user’s IP address. Consider the row for the user, us3. The (true) marks in the relation table indicate that user us3 requested the URLs GDef, GReg, GLog, PLog and GShop. We distinguish a GET (G) request from a POST (P) request when building the lattice, since they are essentially different requests. The first six rows of the table are the user sessions collected initially, and form the original relation table. The last two rows are the user sessions that we intend to analyze incrementally (in Section 4). Based on the original relation table, concept analysis derives the lattice in Figure 1(b(i)) as a sparse representation of the concepts. Attribute sets are drawn just above each node, while object sets are drawn just below each node.

Properties. Lattices resulting from performing concept analysis for test suite reduction will exhibit several interesting properties and relationships.

Interpreting the sparse representation, a user session s requests all URLs at or above the concept uniquely labeled by s in the lattice. For example, the user session us3 requests PLog, GShop, GDef, GReg and GLog. A node labeled with a user session s and no attributes indicates that there are no unique URLs requested by s. For example, us6 requests no unique URL. Similarly, a URL u is accessed by all user sessions at or below the concept uniquely labeled by u. In the example, the URL GShop is accessed by the user sessions us2, us3, us4, and us6.

The ⊤ of the lattice denotes the URLs that are requested by all the user sessions in the lattice. In our example, GReg, GDef and GLog are requested by all the user sessions in our original test suite. The ⊥ of the lattice denotes the user sessions that access all URLs in the context. Here ⊥ is not labeled with any user session, denoting that there is no user session that accesses all the URLs in the context.

To determine the common URLs requested by two separate user sessions s1 and s2, the closest common node c towards ⊤, starting at the nodes labeled with s1 and s2 is identified. All URLs at or above c are those jointly accessed by s1 and s2. For example, URLs jointly accessed by user sessions us3 and us4 are GShop, GDef, GReg, and GLog. Similarly, to identify the user sessions that jointly request two URLs u1 and u2, the closest common node d towards ⊥ starting at the nodes uniquely labeled by u1 and u2 is determined. All user sessions at or below d jointly request u1 and u2. For example, user sessions us3 and us6 jointly request URLs PLog and GShop.

Use for Test Suite Reduction. Test suite reduction exploits the concept lattice’s hierarchical clustering properties. In particular, we developed a heuristic for selecting a subset of user sessions to be maintained as the current test suite, based on the current concept lattice. Given a context with a set of user sessions as objects O, we define the similarity of a set of user sessions Oi ⊆ O as the number of attributes shared by all of the user sessions in Oi. Based on the partial ordering reflected in the concept lattice, if (O1, A1) ≤ (O2, A2), then O1 is more similar than O2. User sessions labeling nodes closer to ⊥ are more similar in their set of URL requests than nodes higher in the concept
Our current heuristic for user session selection, which we call test-all-exec-URLs, seeks to identify the smallest set of user sessions that will cover all of the URLs executed by the original test suite while representing the common URL subsequences of the different use cases represented by the original test suite. This heuristic is implemented as follows: The reduced test suite is set to contain a user session from each node next to /?, that is one level up the lattice from /?. These nodes contain objects that are highly similar to each other. If the set of user sessions at /? is nonempty, those user sessions are also included.

We have performed experimental studies and user session analysis to investigate the intuitive reasoning behind clustering user sessions based on concept analysis and our heuristic for user session selection. These studies examined the commonality of URL subsequences of objects clustered into the same concepts and also compared the subsequence commonality of the selected user sessions with those in the remainder of the suite. The study is described fully in another paper [31]; the results provide support for using concept analysis with a heuristic for user session selection. This approach differs from traditional reduction techniques such as selecting the next user session with most coverage without considering the attributes already covered. In such an approach, no effort is made to choose representatives from different clusters of similar use cases.

In our example in Figure 1, the original test suite is all the user sessions in the original context. The reduced test suite however contains only user sessions us2 and us6, which label the next-to-bottom nodes. By traversing the concept lattice to ⊤ along all paths from these nodes, we will find that the set of URLs accessed by these two user sessions is exactly the set of all URLs requested by the original test suite.

4. Incremental Reduced Test Suite Update

The key to enabling the generation of a reduced test suite with coverage similar to a test suite based on large user session data sets, without the overhead for storing and processing the complete set at once, is the ability to incrementally perform concept analysis. The set of attributes $A$ can be fixed to be the set of all possible URLs related to the web application being tested. The general approach is to start with an initial user session data set, and incrementally analyze additional user sessions with respect to the current reduced test suite. The incremental analysis results in an updated concept lattice, which is then used to incrementally update the reduced test suite.

More specifically, the incremental update problem can be formulated as follows:

Given an additional user session $s$ and a tuple $(O, A, R, L, T)$ where $O$ is the current set of user sessions (i.e., objects), $A$ is the set of possible URLs in the web application (i.e., attributes), $R$ is the binary relation describing the URLs that are requested by each user session in $O$, $L$ is the con-
cept lattice output from an initial concept analysis of \((O, A, R)\), and \(T\) is the reduced test suite with respect to \(L\), modify the concept lattice \(L\) to incorporate the user session \(s\) and its attributes, creating an updated lattice \(L'\) without building \(L'\) from scratch, and then incrementally update the reduced test suite \(T\) to \(T'\) with respect to \(L'\).

Our incremental algorithm, shown in Figure 2, utilizes the incremental concept formation algorithm developed by Godin, Missaoui, and Alaoui [10]. Godin et. al’s incremental lattice update algorithm takes as input the current lattice \(L\) and the new object with its attributes. Once an initial concept lattice \(L\) has been constructed from \(R\), there is no need to maintain \(R\). The incremental lattice update may create new nodes, modify existing nodes, add new edges, and change existing edges that represent the partial ordering. As a result, nodes that were at the next-to-bottom location may now be raised in the lattice, new nodes may have been created at the next-to-bottom location, but existing internal nodes will never “sink” to the next-to-bottom location because the partial ordering of existing internal nodes with respect to the existing next-to-bottom nodes is unchanged by addition of new nodes. These changes are the only ones that immediately affect the updating of the reduced test suite. Thus, test cases are not maintained for internal nodes. The algorithm in Figure 2 is designed to identify the test cases added or deleted from the current reduced test suite. If the software engineer is not interested in this change information, the update can simply replace the old reduced test suite by the new test suite by identifying the new-next-to-bottom-set after incremental lattice update.

Example. To demonstrate the incremental test suite update algorithm, we begin with the initial concept relation table (shown above the double horizontal lines) and its corresponding concept lattice in Figure 1(b)(i). Consider the addition of the user session us7, which contains all URLs except the GBooks. Figure 1(b)(ii) shows the incrementally updated concept lattice as output by the incremental concept analysis. The changes include a new (shaded) node and the edge updates and additions, which move one of the old next-to-bottom nodes up in the concept lattice. Thus, the incremental update to the reduced test suite would be a deletion of the user session us2, and addition of user session us7.

Now, consider the addition of the user session us8, which contains only three URLs as indicated by the last row of the augmented relation table. Figure 1(b)(iii) shows the incrementally updated concept lattice after both of these user sessions have been added. In this case, the new user session resulted in a new node and edges higher in the lattice. The next-to-bottom node set remained unchanged. Thus, the reduced test suite remains unchanged, and the new user session is not stored.

Space and Time Costs. The initial batch concept analysis requires space for the initial user session data set, relation table, and concept lattice. The relation table is \(O(\mid O \times \mid A\mid)\) for an initial user session data set of \(\mid O\) and \(\mid A\) URLs relating to the web application. The concept lattice can grow exponentially as \(2^k \mid O\) where \(k\) is the upper bound on the number of attributes of any single object in \(O\); however, this behavior is not expected in practice [10]. In our application of concept analysis, \(k\) is limited by the number of URLs that any given user session would request relating to the web application; since \(k\) is fixed and a given user in a single session is expected to traverse a small percentage of a web application’s URL set, the space requirements can be viewed as \(O(\mid O\mid)\) with a small constant \(k\). For the incremental reduced test suite update, the relation table is not needed. Space is needed only for the current concept lattice (with objects and attributes), current reduced user session data set, and new user sessions being analyzed.

Time for the batch algorithm is exponential in the worst case, with time \(O(2^k \mid O\mid)\), while the incremental algorithm for our problem where the number of attributes is fixed is \(O(\mid O\mid)\), linearly bounded by the number of user sessions in the current reduced test suite [10].
5. Framework for Web Testing

In order to apply concept analysis to user session data, we constructed an automated prototype framework that enables the generation of a reduced test suite, which can be replayed to generate test coverage reports and perform fault detection studies. The process as illustrated in Figure 3 begins with the collection of user session data (step (1)). This is the web application execution/logging phase of our prototype framework. To obtain user session data, we rewrote the Resin [29] web server’s AccessLog class in order to collect the specific data of interest. In particular, we collected information pertaining to each user request including IP address, time stamp, URL requested, GET/POST data, and cookies. Once the user session data is logged, the process of generating test cases can begin. Note that we define user sessions as beginning when a request arrives from a new IP address and ending when the user leaves the website or the session times out. In addition, we also keep track of the timestamp of the request. Requests from the same IP, but after an interval of 45 minutes are considered as part of a new session.

We assume the access log is provided to a tester (step (2)). Step 3 is essentially the test case generation phase of our framework. It begins with parsing the access log to generate a relation table. Lindig’s concepts tool [19] is then utilized to construct a concept lattice. This tool takes a relation table as input and outputs a lattice. The heuristic for identifying the reduced test suite from the lattice is embedded in the test suite reducer.

In step (4), the Java source files generated by the server, which correspond to the JSP code of the application are instrumented by the Java code coverage tool, Clover [6], constituting our test coverage evaluator. Step (5) is the replay of the reduced test suite. We utilized the GNU Unix utility wget, which supports the non-interactive download of files over the HTTP protocol, as our replay tool. The replay tool is the core of our test case executor/oracle phase of the framework. Additional input parameters to wget include cookie information and POST or GET data associated with the original request in order to maintain application state information. To guarantee consistency in replay, we also restore the state of the database to its original state (i.e., the state before logging) and reset the database before replay. Finally, a coverage report is generated (step(6)). From a software tester’s point of view, the above process provides a tester with the means to automatically generate test cases with real data as input and then replay the test cases, and gather coverage information. Steps (7), (8), and (9) depict the incremental update of the reduced test suite, with a user session from a new access log and the current concept lattice input to the incremental test suite updater, which outputs the updated reduced test suite and updated lattice. Step (5) also plays a role in determining the fault detection capability of the reduced suite against the original suite. The JSP pages retrieved on replaying the test suites (original or reduced) are compared to determine the number of detected faults.
6. Experimental Study

Our initial experimental studies have focused on providing evidence of the potential effectiveness of applying our proposed methodology for automatic, but scalable test case generation. The objective of the experimental study was to address the following research questions.

1. What test case reduction can be achieved through concept analysis for user-session testing?
2. How does reducing the test suite affect replay time and oracle time?
3. What is the cost effectiveness of incremental vs. batch concept analysis for reduced test suite update?
4. Does concept analysis reduce the test suite while maintaining good coverage?
5. How does the reduced test suite fare in terms of fault detection capabilities?

6.1. Experimental Setup

We used an application from an open source e-commerce site [11] to experiment with applying concept analysis to user sessions to generate a reduced test suite. The application is a bookstore, where users can register, login, browse for books, search for specific books giving a keyword, rate the books, buy books by adding them to the shopping cart, modify personal information, and logout. The bookstore application has 9,748 lines of code, 385 methods and 11 classes. Since our interest was in user sessions, we considered only the code available to the user when computing these metrics, not the code that forms part of bookstore administration. The application uses JSP for its front-end and MySql database for the backend.

Emails were sent to various local newsgroups, and advertisements were posted in the university’s classifieds webpage, asking for volunteers to browse the bookstore. We collected 123 user sessions, all of which were used in these experiments. Some of the URLs of bookstore mapped directly to the 11 classes/JSP files and the rest were requests for gif and jpeg images of the application. The size of the largest user session in bookstore was 863 URLs and on average a user session had 166 URLs.

The application was hosted on the Resin web server. User requests can be HTTP GET requests or HTTP POST requests, depending on the page being accessed in the bookstore. The process of collecting user session data differs for each of the HTTP methods. Modifications were made to Resin to allow for logging data from either request.

The setup for the fault detection study consisted of manually seeding faults in the application such that each version of the application contained one seeded fault. The “correct version” of the program was considered to be the expected result (i.e., the set of JSP pages returned as a result of executing the correct version of the program). To detect faults, the pages sent in response by the web server were logged during replay in order for the oracle to determine if a test case passes or fails. We utilized a fine grain text based comparator (diff), which compares the expected output with the actual output. Any differences detected between two pages results in the oracle indicating that a test case failed.

6.2. Effectiveness of Using Concept Analysis

The first experiment involved evaluating the resulting test size reduction and its impact on the cost of executing and validating test cases. We measure reduction in test suite size achieved by applying concept analysis and the time saved during oracle comparisons and replay.

Methodology. Concept analysis was applied on the 123 user sessions collected for the bookstore application and the lattice was obtained. In accordance with our heuristic for test suite reduction, user sessions corresponding to the next-to-bottom nodes were selected to be in the reduced suite. The original suite was comprised of all the 123 user sessions.

Metrics. We evaluated the effectiveness of applying concept analysis to the problem of test suite reduction by comparing the number of test cases (user sessions) in the original and the reduced suite. We assessed the benefits of test suite reduction in terms of the time to replay and time to perform oracle comparison. Replay time is the time required to replay the original or reduced suite of user sessions. Oracle time is defined as the sum of times to reinitialize the database, replay and compare actual versus expected results for one run of the (original or reduced) suite.

Results: In our study, we observed that concept analysis achieved considerable reduction in test suite size. In particular, a reduction of 87.8% in test suite size occurred as can be observed in the first row of Table 1 (Question 1). As observed in rows 2 and 3 of Table 1, the large percent reduction in test suite size also significantly reduces the time to replay the user sessions and perform oracle comparison, respectively (Question 2). When performing fault detection studies for a large number of faults and multiple runs of the suite, this time reduction could prove to be considerable.

6.3. Incremental vs. Batch

This experiment involved assessing the scalability of incremental concept analysis.

Methodology. Initially, the test suite was reduced in batch using the publicly available tool concepts; the original set of user sessions was input to the concept analysis tool...
and the next-to-bottom nodes were chosen for the reduced suite. To perform incremental concept analysis, we first processed 100 of bookstore’s user sessions in batch to obtain a reduced test suite, and then the 23 remaining sessions were incrementally added to the lattice to obtain an updated test suite.

**Metrics.** The evaluation of the effectiveness of incremental concept analysis was achieved by comparing the size of the files required by the incremental and batch techniques to eventually produce the reduced suite. Time costs are not reported for incremental versus batch because we believe it is unfair to compare our implementation of the incremental algorithm, which is an unoptimized and slow academic prototype against the publicly available tool concepts.

**Results.** The batch algorithm required the complete original set of user sessions to derive the reduced test suite. The space for the original set of user sessions was noted to be 3.5MB. Once the initial 100 user sessions were processed in batch, the incremental algorithm maintained only the reduced set when generating new test cases (i.e., the updated test suite). The space for the reduced set was observed to be 894KB, a savings of 74.5% in space. Thus, the incremental reduction process saves space costs considerably by not maintaining the original suite of user sessions (Question 3). In a production environment, the incremental reduction process could be performed overnight with the collection of that day’s user sessions to produce a fresh updated suite of test cases for testing, while still saving the space by keeping a continually reduced suite. A batch analysis of all 123 sessions results in the same reduced test suite as batch analysis of 100 followed by incremental update for the last 23 sessions. This can be shown to hold in general.

### 6.4. Program Coverage

In the next experiment, we examined the resulting program coverage of the reduced suite against the original suite to determine how much coverage is lost due to reduction.

**Methodology.** We used the commercially available tool, Clover to evaluate coverage obtained on replaying the reduced suite and the original suite. On deploying the bookstore application, the Resin web server generates corresponding Java files for each JSP file in the application. We instrumented these Java classes (using Clover) and replayed (using wget) both the original and reduced suite of user sessions. During replay for coverage, we restored the database to the state before logging and resent cookies and name-value pairs recorded during logging the user sessions to make certain that the replay is accurate and the session is maintained by the server.

**Metrics.** The effectiveness of the reduced suite was measured in terms of statement and method coverage.

**Results.** The coverage results obtained after replaying both the original and reduced test suite are presented in Table 1. The percentage of coverage loss with the reduced suite is negligible (Question 4). We attribute this low loss in coverage to the commonality of URL subsequences in objects of the same concept node, the coverage of all URLs that appear in any user session, and the low percent of URL subsequences lost through test selection for short common subsequences (see paper [31]). We believe that common URL subsequences replayed with name-value pairs follow similar paths in the program; part of future work is to examine this relation more closely.

### 6.5. Fault Detection Capability

The last aspect of our study involved evaluating the fault detection capability of the reduced suite compared to the original suite.

**Methodology.** Initially, both the original and reduced suites were replayed through the fault-free application, and the expected results (i.e., JSP pages) were recorded for both runs. A total of 40 faults were then inserted into separate versions of the application. The faults inserted into the code can be broadly classified as: data and control flow based, changes to name-value pairs of the web page and faults in database queries. The original and reduced suites were re-run through the faulty versions and the
actual results were computed. For every user session in each run of the suites, a count of detected faults and list of specific faults discovered by the suites were recorded.

**Metrics.** Comparisons were made based on the number of faults detected by each suite to evaluate how well the reduced suite performed in detecting faults versus the original suite.

**Results.** The last row of Table 1 shows the number of faults detected by the original and reduced suites. The original suite found 7 more faults than the reduced suite. The faults not detected by the reduced suite were mainly related to name-value pairs. This indicates that the fault detection capabilities were not hampered largely by reducing the test suite size. We believe that the reduced suite performs reasonably well in detecting faults, though with some loss (Question 5). We are examining changes to the heuristic to increase the fault detection.

### 7. Related Work

#### 7.1. Concept Analysis in Software Engineering

Snelling first introduced the idea of concept analysis for use in software engineering tasks, specifically for configuration analysis [17]. Concept analysis has also been applied to evaluating class hierarchies [33], debugging temporal specifications [1], redocumentation [18], and recovering components [20, 35, 32, 8].

Ball introduced the use of concept analysis of test coverage data to compute dynamic analogs to static control flow relationships [2]. The binary relation consisted of tests (objects) and program entities (attributes) that a test may cover. A key benefit is an intermediate coverage criteria between statement and path-based coverage.

Concept analysis is one form of clustering. To improve the accuracy of software reliability estimation [27], cluster analysis has also been utilized to partition a set of program executions into clusters based on the similarity of their profiles. Dickinson et al. have utilized different cluster analysis techniques along with a failure pursuit sampling technique to select profiles to reveal failures. They have experimentally shown that such techniques are effective [7]. Clustering has also been used to reverse engineer systems [23, 24, 36].

#### 7.2. Reducing Test Suites

Several test suite reduction techniques have been proposed [13, 5, 25]. The goal is to attempt to reduce the cost of maintaining and executing a large test suite during software maintenance by eliminating test cases that result in covering or executing the same statements in a program. For instance, Harrold et al. developed a test suite reduction technique that employs a heuristic based on the minimum cardinality hitting set to select a representative set of test cases that satisfy a set of testing requirements [13]. Such techniques assume that the entire test suite is complete and associations between test cases and test requirements known before reduction heuristics are applied. Harder et al. [12] proposed a technique to generate, augment and minimize the test suites, but their technique involves dynamically generating operational abstractions, which can be costly.

### 7.3. Web Testing

Several testing tools have been developed to test the appearance and validity of a web application [34]. Recently, web-based analysis tools have been developed that model the underlying structure and semantics of web programs.

With the goal of providing automated data flow testing, Liu, Kung, Hsia, and Hsu [21] developed the object-oriented web test model (WATM). However, the model is developed for HTML and XML documents, and does not consider many features inherent in other web applications.

Ricca and Tonella [30] developed a high level UML-based representation of a web application and described how to perform page, hyperlink, def-use, all-uses, and all-paths testing based on the data dependences computed using the model. However, significant intervention is required by the user for generating input.

Lucca et al. developed a web application model and set of tools for the evaluation and automation of testing web applications [22]. They presented an object-oriented test model of a web application, and proposed a definition of unit and integration levels of testing. They developed functional testing techniques based on decision tables, which help in generating effective test cases. However, the process of generating test input in this manner is not automated.

### 8. Conclusions and Future Work

By applying concept analysis to cluster user sessions and carefully selecting user sessions from the resulting concept lattice, we are able to maintain and incrementally update a reduced test suite for user session based testing of web applications. Our experiments show that quite similar statement and method coverage can be sustained, while reducing the storage requirements. Similar to other experiments [9], our experiments show that there is a tradeoff between test suite size and fault detection capability; however, the incremental update algorithm enables a continuous examination of possibly new test cases that could increase fault detect-
tion capability without the need to ever store the larger set of session data to determine the reduced test suite.

In the short term, our future work includes a more significant empirical investigation of this approach with larger web applications to which we have been kindly given access from the University of Delaware’s IT team, and more extensive user session data. Furthermore, we plan to experimentally investigate the use of alternate heuristics for test case reduction that maintain high fault detection capability.
